We have investigated the differential resistance of hybrid planar Al-(Cu/Fe)-Al submicron bridges at low temperatures and in weak magnetic fields. The structure consists of a Cu/Fe bilayer forming a bridge between two superconducting Al electrodes. In the superconducting state of Al electrodes, we have observed a double-peak peculiarity in differential resistance of the S-(N/F)-S structures at a bias voltage corresponding to the minigap. We claim that this effect (the splitting of the minigap) is due to an electron spin polarization in the normal metal which is induced by the ferromagnet. We have demonstrated that the double-peak peculiarity is converted to a single peak at a coercive applied field corresponding to zero magnetization of the Fe layer.

I. INTRODUCTION

In superconductor–normal metal (SN) bilayers the superconducting proximity effect is responsible for the modification of the electron density of states (DOS) and the appearance of a minigap $\epsilon_g$ in the normal metal.¹ Thereby a normal-metal region close to the SN interface behaves as a genuine superconductor; i.e., there is an energy range $(-\epsilon_g, +\epsilon_g)$ around the Fermi energy in which there are no available states for normal quasiparticles. This theoretical statement¹ was proved reliably in recent measurements of the local DOS.²−⁴ A minigap peculiarity becomes apparent in the differential conductance (resistance) spectra of SNS junctions side by side with the superconducting gap peculiarity of superconducting electrodes.⁵,⁶ In the case of a superconductor-ferromagnet (SF) bilayer the ferromagnetic exchange splitting of the spin subbands results in an energy shift of the corresponding minigap, which is asymmetric for the majority and the minority spin subbands; i.e., one can distinguish two minigap peculiarities in SF-DOS spectra. However, even in the case of diluted ferromagnets the exchange field $E_{ex}$ is very large, so it is difficult to observe the minigap splitting on well-known SF-DOS spectra.³⁻⁴

II. EXPERIMENT

Figure 1(a) shows a scanning electron microscopy (SEM) image of one of our samples together with the measurement scheme. The submicron-scale planar junctions were fabricated by means of the electron beam lithography and in situ shadow evaporation. First, a thin (10–15 nm) iron layer is deposited onto the oxidized silicon substrate, followed by the deposition of a 60 nm thick copper layer, so that in combination the NF bilayer bridge $[0.2 \times (0.3−0.6) \mu\text{m}^2]$ is formed. Subsequently, a thick aluminum layer of around 100 nm is evaporated at a second angle in order to form the superconducting leads. We fabricated samples with different separation length $L$ between the superconducting electrodes, ranging from 30 nm to 300 nm. All transport measurements were performed using the standard four-terminal method. As the specific resistance of the copper film ($\rho_N = 4.5 \mu\Omega\times\text{cm}$) is much smaller than the one of the iron film ($\rho_F = 70 \mu\Omega\times\text{cm}$), the main part of the current flows through the copper layer. The measurements at temperatures down to 0.3 K were performed in a shielded cryostat equipped with a superconducting solenoid. Two stages of RC filters were incorporated into the measurement system to eliminate the electrical noise.

III. EXPERIMENTAL RESULTS

In order to check that the iron layer forms a single domain magnetized along the S-(N/F)-S junction, reference iron structures with the same geometry and sizes as the N/F bilayers, but only with the ferromagnetic layer, were fabricated and subsequently investigated by means of magnetic-force-microscopy imaging (MFM). Figure 2(a) shows a MFM image of the iron bar at zero magnetic field together with the topographical image (AFM). The picture of magnetic poles is similar to the MFM images of iron nanostraps published
in Ref. 12. According to this work we dealt with practically uniform magnetized structure. The main magnetization is directed along the long axis of the rectangle but diverges from a dipolar configuration at the corners.13 Nonlocal spin-valve experiments on similar submicron iron structures indicate single-domain behavior, with coercive fields of about 200–500 Oe for magnetic fields applied along the element.14 To estimate the coercive field of the iron bar S-F-S (Al-Fe-Al) bridges with the same geometry but without the Cu layer were prepared. We have measured the magnetoresistance of the S-F-S bridge at $T = 4.2$ K using an in-plane magnetic field perpendicular to the Fe-bar easy axis [Fig. 2(b)]. The coercive field $H_c$ (about 300 Oe) was determined from the maximum value of the resistance due to anisotropic magnetoresistance (AMR) effect (see, for example, Refs. 15 and 16). The observation of a finite coercive field suggests that the magnetization configuration deviates from the single-domain structure during magnetization reversal.

Resistive and Josephson characteristics of the planar junctions depend strongly on the spacing $L$ between the aluminum electrodes as well as on the total length of Cu/Fe bilayers that were partly overlapped by the electrodes. The characteristics and their discussion will be given in detail in a later work.17 The Josephson supercurrent was observed in structures with $L$ from 30 nm up to 150 nm. It is important to note that the coherent Josephson transport was suppressed significantly by addition of the extra ferromagnetic layer. Figure 3 presents the dependence of the critical current $I_c$ vs $L$ for the Al-(Cu/Fe)-Al junctions shown in Fig. 1 in comparison with the $I_c(L)$ dependence for control Al-Cu-Al structures fabricated by the same procedure but without the additional Fe layer. The critical currents of S-(N/F)-S junctions are much smaller than those for S-N-S junctions.

The weakening of the Josephson effect in S-(N/F)-S junctions with the addition of Fe can be naturally explained by effective spin polarization induced into the N layer. As a result, the effective coherence length in N becomes shorter and Josephson coupling is suppressed. The data of Ref. 19 indicate that the spin-diffusion length in Cu is as large as 1 $\mu$m at 1 K, which is larger than the bridge sizes.

To observe DOS peculiarities of the novel double-proximity structures we measured differential current-voltage characteristics by current-driven lock-in technique as well as the dc current-voltage characteristics of the structures. Figure 4(a) shows the differential resistance vs bias voltage for the Al-(Cu/Fe)-Al junction (S1) with the space $L = 130$ nm between superconducting electrodes at $T = 0.4$ K. The curve is symmetric with respect to the zero bias voltage; therefore only positive voltage values are shown. There are two types of peculiarities on the $dU/dI(U)$ dependence. The first one corresponds to the superconducting gap of aluminum $\Delta = 180$ $\mu$eV and the second one is a double-peak peculiarity at the subgap energy $\varepsilon \approx 60$ $\mu$eV which is much smaller than $\Delta$.

**IV. DISCUSSION**

We suppose that the double-peak peculiarity in S-(N/F)-S transport is due to the presence of two spin-dependent minigaps in the normal-metal interlayer of SNF trilayered electrodes. The easiest way to check this idea with the spin-dependent minigap origin is to change the uniform state of the ferromagnet layer magnetization. The differential resistance of the S-(N/F)-S samples was measured in the presence of magnetic field $H$ which increases from zero by small steps [see Fig. 4(b)]. Magnetic field was applied in plane of the sample perpendicular to the bridge, as it was for S-F-S structures shown in the Fig. 2(b) inset. One can see that at around 300 Oe the separation between the two peaks of the double-peak peculiarity decreases significantly.
a simple solution for the gap splitting but does not change case when F and N films are thin compared to the coherence contact with a ferromagnet. For simplicity we shall discuss the superconductor and magnetic proximity effect due to a spin systems in the N-layer due to the proximity effect from splitting in a SNF-NF structure with a trilayered electrode, magnetic field because of the suppression of superconductivity of the peculiarity is shifted to low voltages with increasing joined to single peak at about 300 Oe [Fig. 4(d)]. The position observed for some samples that the double-peak peculiarity peak becomes single at the voltage applied magnetic field.

The dependence of the double-peak splitting effect effectively reducing the induced exchange splitting in the N layer. The dependence of the double-peak splitting in the N-layer due to the proximity effect from the SN interface with the origin at the boundary between the SNF trilayer and NF bilayer. Equations (1) should be supplemented by the boundary conditions (Ref. 20).

\[
\gamma_{BN} \frac{\partial}{\partial y} \theta_N = -\sin(\theta_S - \theta_N)
\]

at the SN interface with \(\gamma_{BN} = R_B/\rho_N \xi_N\) and

\[
\xi_N \frac{\partial}{\partial y} \theta_N = \gamma \xi_F \frac{\partial}{\partial y} \theta_F, \quad \theta_N = \theta_F,
\]

at the NF interface with \(\gamma = \rho_N \xi_N/\rho_F \xi_F\) (we assumed that the FN interface is transparent). Here \(\sin \theta_S = \Delta/\sqrt{\Omega^2 + \Delta^2}\) and \(\Delta\) is the bulk pair potential of a superconductor. \(R_B\) is the specific resistance of the SN interface; \(\rho_{S,F,N}\) and \(\xi_{S,F,N}\) are the resistivities and the coherence lengths of the S, F, and N layers. We assume that \(\gamma_{BN} \gg \max(1, \rho_S \xi_S/\rho_F \xi_F)\), so that suppression of superconductivity in the S electrode is negligibly small. At the free interfaces derivatives of \(\theta\) functions are zero in the direction of the interface normal.

The problem (1)–(3) is reduced to one-dimensional equations for Green’s functions in the NF bilayer under the S electrode \(\theta_\pm\) (for \(x < 0\)) and Green’s functions for the free FN bilayer \(\theta_+\) (for \(x > 0\)):

\[
\eta^2 \frac{\partial^2}{\partial x^2} \theta_\pm - \sin(\theta_\pm - \theta_\mp) = 0,
\]

\[
\mu^2 \frac{\partial^2}{\partial x^2} \theta_+ - \sin \theta_+ = 0,
\]

where

\[
\eta^2 = \frac{\gamma_{BM} (\gamma k \xi_F^2 + \xi_N^2) \cos \theta_\mp}{\gamma_{BM} (\gamma k \Omega + \Omega) + \cos \theta_S}, \quad \mu^2 = \frac{\gamma k \xi_F^2 + \xi_N^2}{\gamma k \Omega + \Omega},
\]

and \(k = d_F \xi_N/(\xi_F d_N), \gamma_{BM} = \gamma_{BN} d_N/\xi_N\). The solutions of the above equations are

\[
\theta_+ = 4 \arctan \left[ \tan \left( \frac{\theta_0}{4} \exp \left( -\frac{x}{\mu} \right) \right) \right],
\]

\[
\theta_\pm = \theta_\mp + 4 \arctan \left[ \tan \left( \frac{\theta_0 - \theta_\mp}{4} \exp \left( \frac{x}{\eta} \right) \right) \right],
\]

\[
\theta_\pm = \arctan \left[ \frac{\sin \theta_0}{\gamma_{BM} (\gamma k \Omega + \Omega) + \cos \theta_S} \right],
\]

\[
\theta_0 = 2 \arctan \left[ \frac{\sin \theta_\mp}{\cos \theta_\pm + \eta/\mu} \right],
\]

and normalized DOS at energy \(\epsilon\) is given by

\[
\nu = \Re \left[ \cos \theta(-i \epsilon + \delta) \right],
\]
where $\delta = 10^{-3}$ was used in calculations. Figure 5 shows the results of calculation of total DOS (summed over both spin subbands) from Eq. (6). It is seen that the peaks in DOS which for $x < 0$ occur at energies $\varepsilon = \Delta, \varepsilon_+, \varepsilon_-$, transform to dips for $x > 0$. The structure at energies $\varepsilon_{\pm}$ corresponds to minigap splitting due to effective exchange field $h_{\text{ex}} = E_{\text{ex}} v_F d_F/(v_F d_F + v_N d_N)$, where $v_{N,F}$,$d_{N,F}$ are the normal-state densities of states and thicknesses of N and F layers. Interestingly, the double-peak structure at $\varepsilon_{\pm}$ at $x < 0$ transforms to the double-dip structure in the bridge region ($x > 0$) at distances of the order of $\xi_N$. The energy separation ($\varepsilon_+ - \varepsilon_- \simeq \gamma_{BM} h_{\text{ex}}$). For $E_{\text{ex}} = 0$, $h_{\text{ex}}$ is also zero and these features merge into a single peak (dip).

The above results are obtained in the regime of the transparent NF interface ($\gamma_{BF} = 0$). For finite $\gamma_{BF}$, $h_{\text{ex}}$ is renormalized by the factor $[1 + (\gamma_{BF} h_{\text{ex}}/\xi_N)^2]^{-1}$. This factor becomes small for large values of exchange field $h = E_{\text{ex}}/\pi T_c$ in the ferromagnet.

To interpret the observed double-peak structure in the resistance ($dU/dI$), we assume that the SN interface resistance is small compared to the resistance of the NF bridge connecting S electrodes; i.e., the electric field is distributed in the bridge area. In this case, the approach developed in Ref. 21 allows us to take into account nonequilibrium quasiparticle distribution in the NF bridge. In one-dimensional geometry and zero-temperature limit, the resistance is given by the expression

$$dU/dI = R_N \frac{1}{L} \int_0^L \frac{dx}{M(x + eV, x)},$$

where $R_N$ is the normal-state resistance of the bridge and $M(x) = |\text{Re} \cos \theta(x)|^2 + |\text{Re} \sin \theta(x)|^2$ is the effective diffusion coefficient which has contributions from the normal DOS $\text{Re} \cos \theta$ and anomalous DOS $\text{Re} \sin \theta$. The latter has a behavior qualitatively similar to that of a normal DOS at subgap energies. Therefore, since $dU/dI \sim M^{-1}$, it is clear that the double-dip structure of the DOS in the bridge area shown in Fig. 5(b) should manifest itself as a double-peak structure in the resistance $dU/dI$ vs $U$ similar to that observed experimentally [see Fig. 4(a)]. Quantitative calculation of $dU/dI$ is beyond the frame of our model due to the complex device geometry and a number of unknown parameters.

V. CONCLUSION

To conclude, we have observed experimentally a manifestation of the superconducting minigap splitting in the N layer in contact with both the superconductor and ferromagnet in the complex planar S-(N/F)-S system formed by the Al-(Cu/Fe)-Al submicron-size bridge. Such a splitting has to exist in SF bilayers also, but it is difficult to observe it there because of the large values of the exchange field for conventional ferromagnets. It has been demonstrated that the splitting occurs only for contacts to ferromagnetic layers with uniform magnetization and disappears when the applied magnetic field is close to the coercive field.
